

Evaluation of clouds in large-scale models

What? Why? How?

Christian Jakob & Jean-Louis Dufresne

The purpose of the three lectures

- * **Motivate** model evaluation and diagnosis.
- * Provide insight into **key approaches and techniques** of large-scale model evaluation with a focus on **concepts rather than details**.
- * Provide **some results on the current state-of-the-art** in modelling cloud-related variables in climate models.

Motivation

- * **We have built a model by**
 - * choosing the equations
 - * choosing coordinate systems
 - * choosing numerical methods
 - * choosing physical parametrizations
- * Here we **limit ourselves to global models in which clouds and precipitation are parametrized.**

Parametrizations

What is model evaluation?

- * **Models are used in many different ways:** Predictions at many time scales, research tools, ...
- * In the broadest sense, **model evaluation is about measuring how fit for purpose a particular model is.**

What is fit for purpose?

Questions for model evaluation

- * Does the model meet the **needs of the application** and to what extent, e.g., prediction?
- * What are the **limits of its applicability**, e.g., ENSO?
- * What are the **key errors influencing the performance** in the model application?
- * What are the **causes of these errors**?

What is the truth?

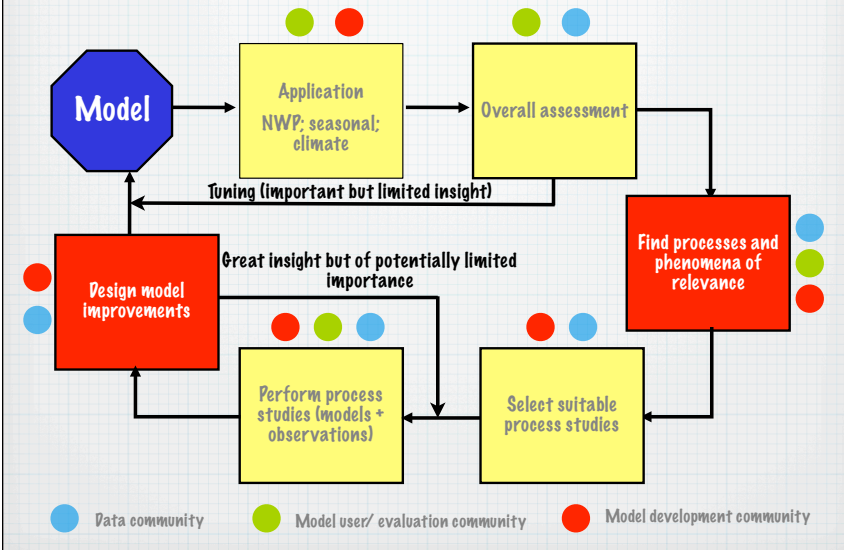

- * Model evaluation usually **needs an estimate of the "truth"**...

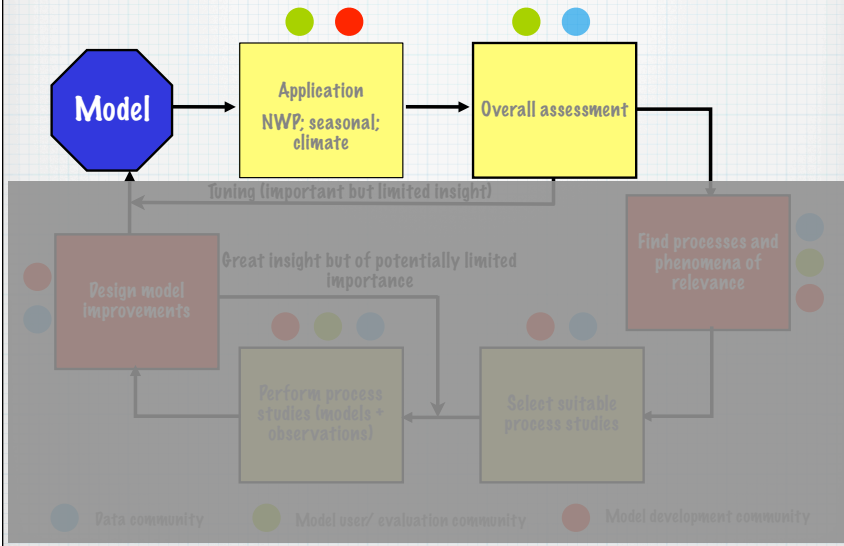

Limits of model evaluation

- * Model evaluation usually **needs an estimate of the truth** and is hence limited by observations and knowledge.
- * There is **no one-fits-all method** of model evaluation. Many **different approaches need to be combined** depending on purpose.
- * **Connecting model error to model formulation** is one of the most **difficult** but often most desirable tasks of evaluation.

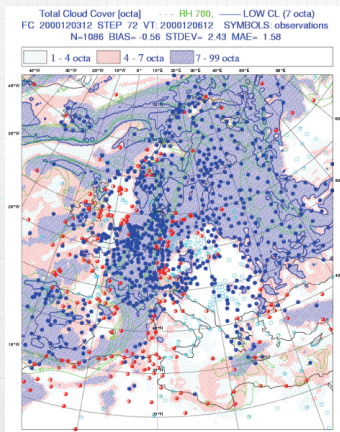

Approaches to model evaluation

Approaches to model evaluation

3-day cloud forecasts

ECMWF 72-h cloud forecast for 3 Dec 2000

Mean errors

For example:
 f_n - Forecast at point n
 o_n - Observation/Analysis at point n

Mean error (Bias) $ME = \frac{1}{N} \sum_{n=1}^N (f_n - o_n)$

Mean absolute error $MAE = \frac{1}{N} \sum_{n=1}^N |f_n - o_n|$

Model assessment in its application

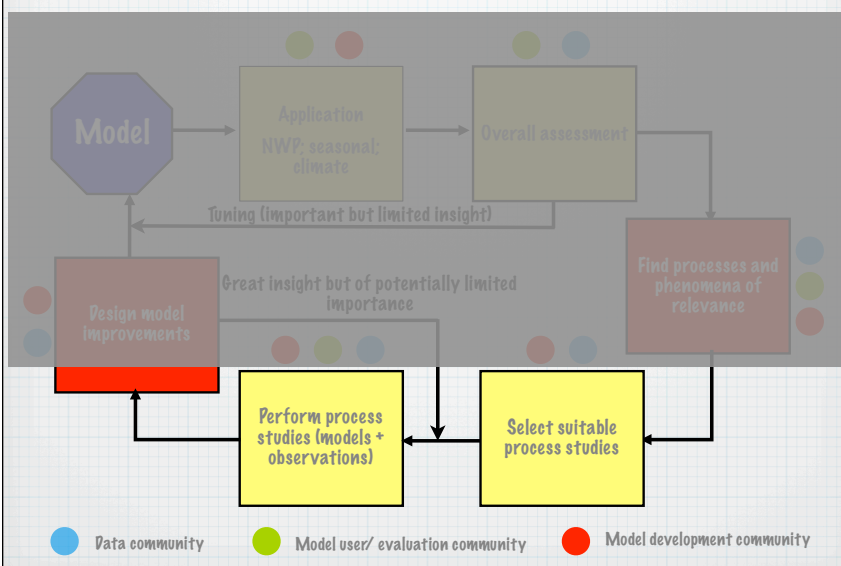

* Pros:

- * assesses what we care about
- * provides insight into limits of applicability of the model

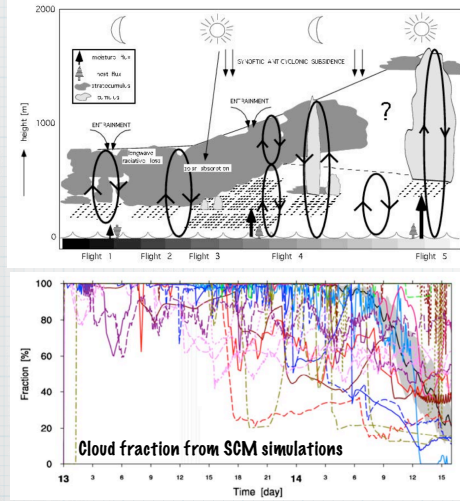

* Cons:

- * provides very little insight into causes of model error

Approaches to model evaluation

"Process" studies

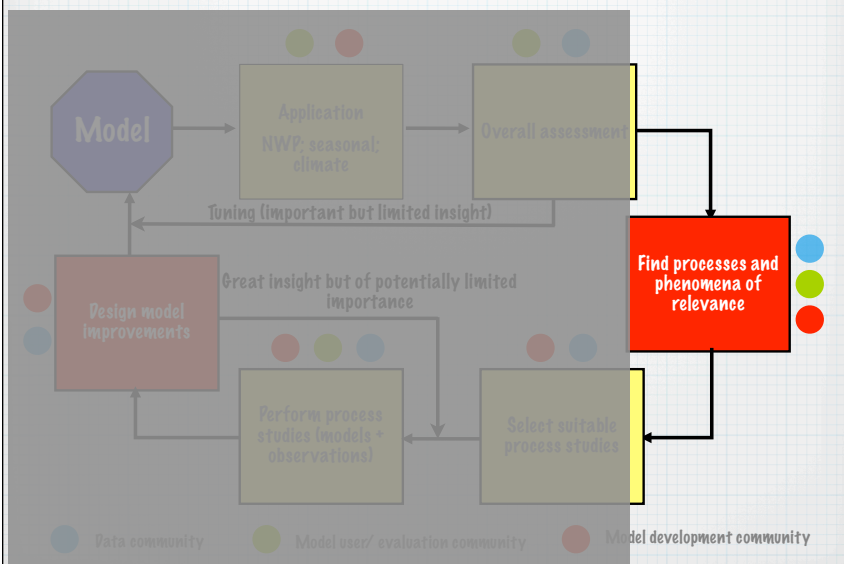

- * Process studies aim to **isolate parts of the system** to study it in detail.
- * "Truth" usually comes from **field experiments** in which many detailed observations are available.
- * **Complex cloud models** as well as so-called **single column models** are often applied to simulate parts of the observed period
- * Detailed comparisons at the "process level" can then be performed.

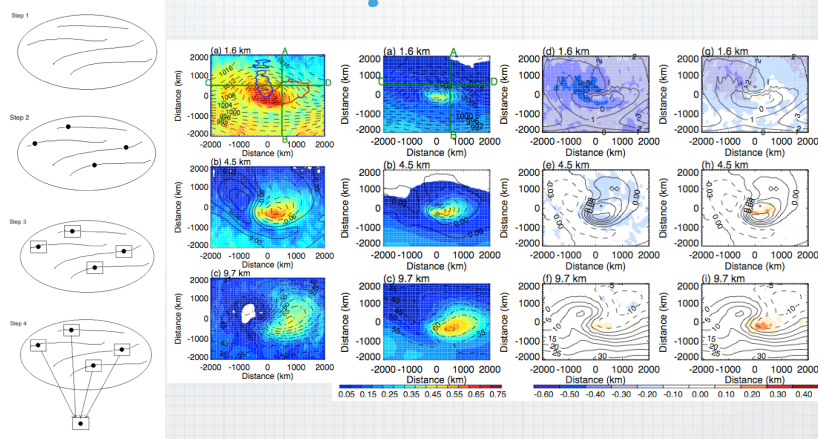

Process studies

- * **Pros:**
 - * allow detailed assessment of individual model processes
 - * might provide great insight as to why things are happening
- * **Cons:**
 - * link to overall model errors is not always clear
 - * better process representation does not guarantee better model results

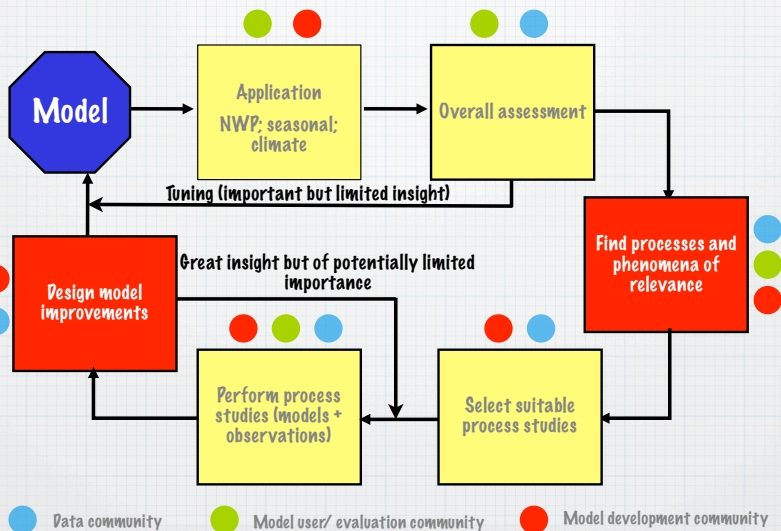

Approaches to model evaluation

Example: Cyclone Composites

Model evaluation is a community effort

Qualitative vs quantitative evaluation

- * Model evaluation can be **“qualitative”** or **“quantitative”**. Both are useful.
- * **“Qualitative”**: Compare plots and make subjective assertions on the quality of the model. Useful when a priori knowledge can be included into the assessment. Subjective part may introduce extra problems (e.g., rose-tinted glasses.)
- * **“Quantitative”**: Calculate objective skill measures. Useful when comparing models or model versions to each other and when monitoring the evolution of a model over long periods of time. Can mislead if used unqualified.

"Quantitative" Evaluation

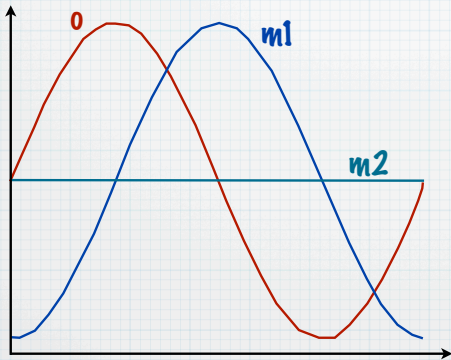

Courtesy of ECMWF. Adapted and extended from Simmons & Hollingsworth (2002)

500 hPa geopotential height anomaly correlation score for the ECMWF model updated from Simmons and Hollingsworth (2002)

Quantitative evaluation

... is not always as simple as it seems!

$$o = \sin(x) \text{ for } 0 < x < 2\pi$$

$$m1 = \sin\left(x - \frac{\pi}{2}\right) \text{ for } 0 < x < 2\pi$$

$$m2 = 0$$

$$RMSE = \sqrt{\frac{1}{N} \sum_{n=1}^N (m_n - o_n)^2}$$

$$RMSE_1 = 1$$

$$RMSE_2 = 0.7$$

So which is the better model?
